Tobacco Smoking As A Possible Etiologic Factor In Bronchiogenic Carcinoma
A Study of Six Hundred and Eighty-Four Proved Cases
Ernst L. Wynder and Evarts A. Graham

General Increase.—There is rather general agreement that the incidence of bronchiogenic carcinoma has greatly increased in the last half-century. Statistical studies at the Charity Hospital of New Orleans (Ochsner and DeBakey), 1 the St. Louis City Hospital (Wheeler) 2 and the Veterans Administration Hospital of Hines, Ill. (Avery) 3 have revealed that at these hospitals cancer of the lung is now the most frequent visceral cancer in men.

Autopsy statistics throughout the world show a great increase in the incidence of bronchiogenic carcinoma in relation to cancer in general. Kenneway and Kenneway, 4 in a careful statistical study of death certificates in England and Wales from 1928 to 1945, have presented undoubted evidence of a great increase in deaths from cancer of the lung. In this country statistics compiled by the American Cancer Society show a similar trend during the past two decades. 5

Tobacco as a Possible Cause of Increase.—The suggestion that smoking, and in particular cigarette smoking, may be important in the production of bronchiogenic carcinoma has been made by many writers on the subject even though well controlled and large scale clinical studies are lacking. Adler 5 in 1912 was one of the first to think that tobacco might play some role in this regard. Tylecote, 6 Hoffman, 7 McNally, 8 Lickint, 9 Arkin and Wagner, 10 Rollo 11 and Maier 12 were just a few of the workers who thought that there was some evidence that tobacco was an important factor in the increase of cancer of the lungs. Müller 13 in 1939, from a careful but limited clinical statistical study, offered good evidence that heavy smoking is an important etiologic factor. In 1941 Ochsner and DeBakey 14 called attention to the similarity of the curve of increased sales of cigarettes in this country to the greater prevalence of primary cancer of the lung. They emphasized the possible etiologic relationship of cigarette smoking to this condition. In a recent paper Schrek 15 concluded that there is strong circumstantial evidence that cigarette smoking is an etiologic factor in cancer of the respiratory tract and finds that his data are in agreement with the results of a preliminary report presented by Wynder and Graham at the National Cancer Conference in February 1949. 16

Purpose of Study.—The purpose of the present study was to attempt to determine, so far as possible by clinical investigations, statistical methods and experimental studies, the importance of various exogenous factors that might play a role in the induction of bronchiogenic carcinoma. In this regard we intended to learn the relative importance of previous diseases of the lungs, rural and urban distribution of patients, various occupations and hereditary background as well as smoking habits. By ob-

The Landmark Interviews

The Lethal Connection: Smoking And Lung Cancer

In February 1949, Ernst Wynder, then a medical student at Washington University in St. Louis, and Evarts Graham, then a well-known lung surgeon also in St. Louis, presented the first data establishing a link between smoking and lung cancer to surgeons at a meeting of the American Cancer Society in Memphis, Tenn.

They got an unexpected reaction. "I had about five minutes...

continued on page 65

At the time of publication of this paper, the authors were in the Department of Surgery, Washington University School of Medicine and Barnes Hospital in St. Louis. Ernst Wynder is currently the president of the American Health Foundation in New York. Evarts Graham died in 1957.

The study on which the original paper was based was aided by a grant from the American Cancer Society.
the results in this report have not been obtained from hospital records since we learned at the outset of our study that the routine records did not supply satisfactory answers to our questions. It was therefore decided to seek the desired information by special interviews. Six hundred and thirty-four patients reported on in this paper had been personally interviewed, and in 38 cases we obtained the information by mailing a questionnaire. In the remaining 17 cases information for the questionnaire was obtained from a person who had been intimately acquainted with the patient throughout his adult life.

Through the cooperation of many hospitals and physicians throughout all parts of the country who permitted us to interview their patients, it is felt that a fairly good cross section of the entire United States has been obtained. The list of cooperating institutions and physicians is presented below. 19

In order to make this survey as uniform as possible, each interviewer used the questionnaire shown in table 1.

In regard to smoking habits, we considered it particularly essential to learn how much a patient had smoked formerly, even though he might not smoke at all or smoke little at the time of the interview. The reason for this is the well known existence of a time lag between the exposure to a carcinogenic substance and the appearance of cancer. Many patients coming into the hospital with chronic disease of the lungs had stopped smoking months, or even years, previously. We therefore asked the patients to estimate the average use of tobacco during the last twenty years of their smoking period. The control patients were questioned in an identical manner; thus any possible error lying in this method of estimating smoking habits was balanced.

In questioning patients about occupations, we attempted to learn all the occupations of a given patient, the years during which he had held these jobs and to what type of dusts or fumes he had been exposed. Similar details were obtained in regard to other possible exposures, such as those a patient might have had in connection with certain hobbies.

Classification of Smoking.—In order to facilitate a statistical analysis of the results, the arbitrary classification of smoking habits given in table 2 was established. If a patient smoked for less than twenty years, his amount of smoking was adjusted to a twenty year period. Thus a patient smoking 20 cigarettes for ten years only was classified as smoking 10 cigarettes daily (class 2). Such adjustments were rarely necessary, since only a few patients had smoked for less than twenty years.

If a man smoked habitually more than one type of tobacco during the last twenty years, the various types were added together to make up his classification. Thus a man who smoked 1 package of cigarettes daily, as well as 2 cigars, was classified as a class IV, or an excessive, smoker.

Histologic Types.—To insure an undoubted diagnosis, microscopic confirmation of the presence of carcinoma was obtained in all cases. Some difficulty arose in the histologic classification because of the variation of terms employed by pathologists in the different hospitals who examined the specimens. For example, what some pathologists would designate as an adenocarcinoma others would classify as an undifferentiated carcinoma. Likewise, the term oat cell or round cell carcinoma was at times used, a designation which is not recognized by some pathologists. In some cases pathologists called a lesion, from biopsy section, merely a carcinoma, unclassified. It may be said, however, that in general by far the most prevalent histologic types were the epidermoid or squamous carcinoma and its variant the undifferentiated carcinoma. These are the most common types found in males. In females the adenocarcinoma has so far been nearly as common as the other types. It is unquestionably the epidermoid and undifferentiated carcinomas which have shown the greatest increase in recent years. For this reason we were particularly interested in study.

ing these types separately from the adenocarcinomas. The present report includes 695 male and 25 female patients with epidermoid, undifferentiated and unclassified carcinomas and 39 male and 15 female patients with adenocarcinoma. In order to determine possible sex variations in the etiology of cancer of the lung, results in men and women are reported separately.

Control Study 1.—To check all possible bias on the part of the interviewers who saw only patients believed to have bronchiogenic carcinoma, it was deemed advisable to conduct a control study in which a nonmedical investigator would interview every patient admitted to the Chest Service of Barnes Hospital without knowing the diagnosis in advance. Two interviewers were used for this purpose. When the final diagnosis was determined, all cases of cancer of the lungs (75 men) were separated from the other cases (132). Control patients under the age of 30 were excluded since there were no cases of cancer in this age group. Seventeen male patients for whom no definitive diagnosis could be made were also omitted.

In addition these interviewers interrogated patients with cancer of the lung at other St. Louis hospitals, also without previous knowledge of diagnosis. Here the interviewers were given the names of several patients with diseases of the chest in a comparable age group, of whom at least 1 was suspected to have bronchiogenic carcinoma. The patients with proved cancer of the lung (25 men) and the other patients (54 men) were added to the Barnes Hospital groups, thus collectively making up control study 1.

To determine the smoking habits, as well as the other data contained in the questionnaire of our study of other hospital patients, the nonmedical investigators also questioned patients without cancer of the lungs on the general surgical and medical service at Barnes Hospital, the Jefferson Barracks Veterans Hospital and the St. Louis City Hospital. This group, called "general hospital population," consists of 780 patients. Also a total of 552 female patients without cancer of the lungs have been interviewed as control patients on our surgical and medical services.

Two objects were to be realized by this control study. One was to learn of possible exposures to exogenous irritants of a large group of patients without cancer of the lung and the other to test the validity of the interviews continued from page 63
to present the data, after which the chairman asked if anybody would like to comment," says Wynder, now president of the American Health Foundation in New York. "Nobody asked a question, nobody commented. People didn't believe it, or else they didn't want to hear about it."

Wynder's idea went against powerful prejudice among physicians of the day. Before he even began his study, Wynder knew that he would need the backing of a reputable scientist. Fortunately, Graham, now deceased, took a gamble and gave Wynder that backing. Their resulting paper, published in The Journal of the American Medical Association (JAMA) in 1950, is featured in this month's Landmarks.

Since then, Wynder has authored more than 600 papers on cancer research and prevention. He established the Division of Epidemiology at Sloan-Kettering Institute for Cancer Research in New York, and in 1969, he founded the American Health Foundation. So despite the cool reaction in Memphis, that meeting marked the beginning of an extraordinary career dedicated to understanding and preventing cancer.

In the following interviews, Donald Shopland, coordinator for the Smoking and Tobacco Program at the National Cancer Institute and former director of the federal government's Office on Smoking and Health, discusses Wynder's paper and his contributions to science and public health. Wynder gives a personal account of his landmark study and his subsequent work at the American Health Foundation.

Donald Shopland

"The study by Wynder and Graham was of seminal importance because it identified the cause of the rapid increase in lung cancer that everyone was worried about in the late 1940s and early 1950s," says Shopland. "Their discovery was of no less public-health significance than finding the cause of smallpox or diphtheria. It was a major breakthrough. I contend that their study should have made Wynder a candidate for the Nobel Prize."

"This study was one of the first to use the case-control method of epidemiological research. It identified a high relative risk for lung cancer in smokers and included women as well.

"At the time the study was published, there was a lot of activity taking place on the subject. In the same issue of JAMA, another study by Morton Levin appeared, linking smoking and lung cancer. And several months later, another study by British scientists [Richard Doll and [Bradford] Hill appeared in the British Medical Journal."

"Wynder later began working with Dietrich Hoffmann, now at the American Health Foundation, to study tobacco carcinogenesis in rats. They painted rats with tobacco tar and were able to produce tumors and papillomas. As a
Fig. 1.—Control study I. Amount of smoking in percentage among 100 male patients with cancer of the lungs (solid bars) and 186 male patients with other chest diseases (lined bars) having the same age and economic distribution.

Fig. 2.—Control study II. Percentages for amount of smoking in 83 cases of cancer of the lungs collected independently by Dr. E. J. Shabart (Chicago), Dr. C. T. Surington (Cleveland), Dr. H. G. Turner (New York) and Dr. G. W. Ware (Boston).

made by those who knew the suspected diagnosis in a given case in advance.

Age Distribution in Control Cases: For proper statistical evaluation of a study of this kind it is obvious that the age distribution should be the same in the control cases as in the cases of cancer of the lungs. Since no patients with cancer of the lungs below 30 or above 80 years of age were seen, no controls beyond these ages have been included. The controls comprised the unselected patients as they entered the Barnes Hospital and other St. Louis hospitals. For that reason their age distribution is not identical with that of the patients with cancer. In order to be able to evaluate the cases without cancer on the basis of the same age distribution as that found in the cases of cancer, the following adjustments were made:

The combined results include data on 780 cases without cancer. Among these there is the following age distribution: 30 to 39, 18.7 per cent; 40 to 49, 21 per cent; 50 to 59, 26.9 per cent; 60 to 69, 20.5 per cent, and 70 to 79, 12.8 per cent. (For the age distribution in the 605 cases of cancer see table 6.)

The smoking classifications of the control cases have been made proportional to the age distribution among the cases of cancer by multiplying the percentage value of each smoking classification for each age group of the controls by the proportion of cases of cancer in that age group. For example, in the age group 30 to 39 of the controls there were 146 (18.7 per cent) patients, of whom 20 (13.6 per cent) were nonsmokers. However, since of the patients with cancer only 2.3 per cent fell into this age group, the value of 13.6 per cent was made proportional to the age distribution in the cases of cancer (2.3 per cent). In a similar manner the smoking values for the control group aged 40 to 49 were made proportional to 17.4 per cent. Finally, the quotients of the smoking classifications in each age group were added to make the percentage values shown in figure 3. The detailed data which compare the smoking classifications of the two groups according to age are shown in table 6. It was from those data that the proportional values were obtained.

The 100 cases of cancer and the 186 cases of control study I were made proportional in the same manner.

Control Study II.—In addition to the control study just cited, it was thought to be valuable to have other physicians carry out similar interviews using our questionnaire. It was thought that the results would serve as an effective control for the cases collected under our own supervision. At this time we are reporting preliminary results based on 83 patients interviewed at the Bellevue Hospital, Columbia University Division (New York), by Dr. H. G. Turner, at the Boston City Hospital by Dr. G. W. Ware, at the Crile Veterans Hospital (Cleveland, Ohio) by Dr. C. T. Surington, and at the Veterans Administration Hospital, Hines, Ill., by Dr. E. J. Shabart.

RESULTS

The first data to be presented are based on 605 proved cases of bronchiogenic carcinoma in men, other than adenocarcinoma. Five hundred and ninety-five of these cases have been diagnosed on the basis of tissue biopsy, 9 on the basis of examination of sputum and 1 on the basis of study of the pleural fluid.

Comparison of Independent Studies.—Before the smoking habits of the 605 patients with cancer of the lungs are compared with those of the general hospital population, it might be well to compare the results in the two control studies and the group of 422 patients (study III) interviewed and collected by one of us (E. L. W.) to determine any possible bias in cases in which the suspected diagnosis was known in advance and whether the data are sufficiently similar to warrant their discussion as a group.

Control Study I: This group consists of 100 patients with cancer of the lungs and 186 with diseases of the chest other than cancer interviewed by two nonmedical investigators who had no previous knowledge of the diagnosis in a given case. The data show no nonsmokers (fig. 1) among the cancer group, while there are 14.1 per cent nonsmokers among the patients with other thoracic diseases. Ninety-five per cent of the patients with cancer are in the classification of moderately heavy to chain smokers and 50 per cent are excessive and chain smokers, while among the patients without cancer, 75.3 and 23 percent, respectively, fell among those smoking groups.

Control Study II: The data in table 3 cover 83 male patients with cancer of the lungs interviewed independently by physicians in other cities. Among each small group of cases some variation is, of course, to be expected. In each of the individual groups nearly half or more of the patients are excessive or chain smokers. Grouping the data of the four independent investigators together, we find 2.4 per cent nonsmokers and 93.9 per cent moderately
heavy to chain smokers (fig. 2), while 59 per cent are excessive and chain smokers. The results of the two-control studies correspond closely to one another as well as to the results of study III (table 4).

The results in relation to the areas or hospitals where the cases were observed show uniformity. Small differences between the groups may well be explained on the basis of the small size of each series. The mountain state series includes 13 patients of Mormon faith. Mormons in general were found to smoke much less than our general hospital population. Among the Mormon patients with cancer of the lung, however, there was only one nonsmoker (72 years old). The others were long-time users of tobacco.

Comparing the three studies, we note little difference. For example, nonsmokers account for 0.0 per cent in control study I, 2.4 per cent in control study II and 1.4 per cent in study III. The percentage of heavy to chain smokers in these three groups is 88, 86.7 and 85.2 respectively, while the percentage of excessive and chain smokers totals 53, 59 and 49 respectively.

Since we thus have not been able to determine any essential difference in the amount of smoking in the three studies, we shall from here on refer to the total results of 605 cases.

Age Distribution.—The age distribution of cancer of the lungs in the present series shows 2.3 per cent of the patients to be under 40 years of age, while 79.3 per cent were 50 years or older (table 5). This distribution readily shows that it would be of little value to study the smoking habits of the younger age groups for the purpose of control studies, since in them, for reasons still unknown to us, cancer of the lungs is a rare phenomenon.

Combined Data on Amount of Smoking.—The data on the amount of smoking among 605 patients with cancer of the lungs and 780 male patients with other diseases reflect the results of the individual studies reported. It may also be noted that there is no essential difference in the amount of smoking between the general hospital population and patients with diseases of the chest who do not have cancer. The total results show that whereas there are 14.6 per cent nonsmokers among the male general population there are 1.3 per cent nonsmokers among the male patients with cancer of the lungs; and while there are 54.7 per cent heavy to chain smokers and 19.1

continued from page 65

result of Wynder's and others' work, Reader's Digest started a series of popular articles describing what these increased health risks meant to the general population. That really got the public's attention.

"The Wynder study caused other scientists to begin using a prospective-study approach to smoking and lung cancer, as opposed to the retrospective studies that Wynder and others had done. In the early 1950s, investigators from the United States and from the United Kingdom began enrolling healthy populations into studies designed to follow mortality over time. The findings from those studies were released in the mid-1950s and reconfirmed the smoking-lung cancer connection that Wynder had found.

"Wynder has really been a leader in this field. His studies have continued, and one of his more recent programs at the American Health Foundation is a school-based program to keep kids from taking up smoking. I think one of the things that has handicapped NIH's ability to have any great influence on cancer death rates is that we continued to support the basic science programs without taking some responsibility for translating that research into public health programs. So in this respect, Wynder has been a real pioneer."

**Ernst Wynder**

"In 1948, I was on fellowship grant, in my sophomore year, with Mark Norton at New York University. The idea struck me that it would be useful to do a case-control study on lung cancer. I went across the street to Bellevue and asked for permission to interview lung-cancer patients and some control patients. I was given permission. I developed a questionnaire, interviewed a couple dozen patients; and it became clear early on that there was a very positive association between smoking and lung cancer."

"I went back to St. Louis [after the fellowship] and introduced myself to Dr. Evarts Graham, who was the chief of surgery at Washington University and well-known for his lung-cancer surgery. He gave me permission to interview his patients during my junior year. During the Christmas vacation, I went to the American Cancer Society [ACS] in New York and met with the medical director at that time, Dr. Charles Cameron. He agreed to give me a grant to expand my studies. I suppose I was one of the few junior medical students to receive a grant from ACS. With this fund, I was able to hire an interviewer. Not only did we begin to interview many more patients, I was able to travel around the United States to interview patients in various cities. Our new data confirmed the association between smoking and lung cancer.

"The first presentation we made on our data was in February 1949, at a meeting of the ACS in Memphis. We presented 200 cases and concluded that smoking was an important factor in the development of lung cancer. I must say that very lit..."

*The percentages for the general male hospital population are given in the left hand columns.

per cent excessive and chain smokers among the general hospital group there are 86.4 and 51.2 per cent, respectively, among the patients with cancer. All these differences seem highly significant.

The results on the amount of smoking according to age groups (table 6) show that in general the patients with cancer of the lungs in their forties and early fifties have smoked more heavily than the older patients with this disease. This observation does not seem to apply to the few patients in their thirties. The age group 70 to 79 has the greatest percentage of light and moderately heavy smokers.

The frequency of nonsmokers in the age groups shown for the patients without cancer is significantly different from that among patients with cancer in the same age groups. However, in the 30 to 39 age group the smoking habits of the patient with cancer are difficult to evaluate since too few patients of this age have been seen.

In comparing the amount of smoking among the various age groups, one must also consider the type of tobacco used, which has undergone a marked shift particularly when the youngest and oldest age groups are considered.

Statistical Analysis of Data.—The statistical analysis of these data has been carried out by Dr. Paul R. Rider, professor of mathematics at Washington University, and H. David Hartstein, M.A., instructor of statistics at Washington University.

On the assumption that smoking has no effect on the induction of cancer of the lungs, the probability (p) of a deviation from expectation as great or greater than that observed is as follows:

Control Study I: Class O, p = 0.0002; class O plus class 1, p = 0.0002; classes 3 to 5 inclusive, p = 0.0226, class 4 plus class 5, p = 0.0002; class 4, p = 0.0046, and class 5, p = 0.0016.

Combined Results: The values for the combined results of 605 patients with cancer of the lung as compared with 780 men in the general hospital population are as follows: class O, class O plus class 1, classes 3 to 5 inclusive, class 4 plus class 5, class 4 and class 5 have p values which are in all cases less than 0.0001.

Their conclusion is as follows: “On the basis of the statistical data for both the control study I and the combined results, when the nonsmokers and the total of the high smoking classes of patients with lung cancer are compared with patients who have other diseases, we can reject the null hypothesis that smoking has no effect on the induction of cancer of the lungs. If smoking does not have anything to do with the induction of cancer of the lungs, then the observed deviation could occur only with the probability (p) as shown above.”

Miscellaneous Data.—Nearly all (98.7 per cent) the cigarette smokers of the cancer group, but fewer pipe (62.5 per cent) and cigar (18 per cent) smokers, stated that they inhaled consciously. Seventy-eight and a half per cent of cancer patients interviewed stated that they usually began to smoke before breakfast.

Type of Tobacco: Among the general hospital population pipes and cigars were smoked most prominently in the older age groups. For example, only 4.3 per cent of the smokers in the age group 30 to 39 used chiefly pipes or cigars, 11.0 per cent in the age group 40 to 49, 12.9 per cent in the age group 50 to 69, 30 per cent in the age group 60 to 69 and 38 per cent in the age group 70 to 79. Only those patients were tabulated as either pipe or cigar smokers who smoked a given type of tobacco predominantly over the last twenty years of their smoking period. Among the age-adjusted general hospital population we find 12.4 per cent pipe smokers and 7.8 per cent cigar smokers and among the patients with cancer 4.0 per cent and 3.5 per cent respectively (fig. 4).

The average age of the pipe smokers with cancer of the lung was 60.5, with a range of 52 to 78, and the average age of the cigar smokers with cancer of the lung was 63.1, the range being from 53 to 76. The average number of pipes smoked by the cancer patients was 15.6
and the average number of cigars 6.8 per day for the last twenty years of their smoking history. This amount of smoking is decidedly higher than that found among the general cigar and pipe smokers.

Duration of Smoking: The duration of smoking in years dates to the first time the patient began smoking habitually to any degree. Of 605 patients with cancer in our series, 96.1 per cent had smoked for twenty years or more, 86.4 per cent for thirty years or more, 68.2 per cent for thirty-five years or more and 50.2 per cent for forty years or more. One patient with epidermoid cancer began to smoke at 45 (20 cigarettes a day), and clinical symptoms of cancer of the lung developed at 50 (class 1 smoker). He had no other exposure to irritants. Only three of the patients with bronchiogenic cancer began to smoke after the age of 25 (fig. 5).

Adenocarcinoma in Men: Among 39 men with adenocarcinoma there were 4 nonsmokers (10.3 per cent), a percentage higher than that found for the other types of bronchiogenic carcinoma. There were 7 chain smokers (18 per cent), significantly more than in the general male hospital population. Ten and three-tenths per cent were excessive, 38.5 per cent heavy, 15.4 per cent moderately heavy and 7.7 per cent light smokers. Among the latter there were 2 minimal smokers.

Data on Women: Among 13 women with adenocarcinoma and 2 designated as having terminal bronchiolar carcinoma there was not 1 heavy smoker. Thirteen were nonsmokers and 2 light smokers. Among 25 patients with epidermoid and undifferentiated carcinoma, however, there were 15 smokers of many years’ duration as well as 10 nonsmokers. Among those who smoked there were 1 light, 4 moderately heavy, 6 heavy, 2 excessive and 2 chain smokers.

To determine the smoking habits among women in the general hospital population 552 patients without cancer of the lung have been interviewed at this hospital. The data resulting from this study show that few women in the cancer age have been heavy smokers for many years and that most of the heavy smokers are young women. On the basis of our arbitrary smoking classification, we found 79.6 per cent of the women to be nonsmokers while 11.3 per cent were moderately heavy to chain smokers, and only 1.3 per cent of the controls in the cancer age were excessive or chain smokers for at least twenty years (fig. 6).

COMMENT

Universal Increase.—If one feels that the greatly increased incidence of cancer of the lungs is real and that this increase is most marked in men, one may theorize

---

continued from page 67

...the attention was paid to our study by the people in the audience. We published our paper in JAMA in May 1950. I probably wouldn’t have gotten any attention, or, for that matter, I might never have been published in those days, without Dr. Graham’s name on the paper. He was a major figure in cancer surgery. At first, he thought that maybe there wasn’t too much to my idea, but later on, he became very supportive of my work. And lucky for me, I worked in an institution with such a famous person who was supportive of my findings, even though his close associate Thomas Burford told him that smoking couldn’t possibly cause lung cancer. So it was certainly fortunate for my career that Dr. Graham sided with a medical student rather than his associate. Dr. Graham was, incidentally, a smoker until 1961. And ironically, even though he did the first surgery on lung cancer (in 1933), he died of lung cancer himself in 1967. Dr. Burford, also a heavy smoker, died some years ago of emphysema.

"It was not until 14 years after our paper was published that the first surgeon general's report confirmed that our conclusion was right. Even in 1933, when we produced for the first time cancer of the skin in animals [by] using tobacco tar—which we reported in Cancer Research—we didn’t get much attention. There was little recognition that in the absence of smoking, lung cancer would have been just as rare as it was at the beginning of the century. The same kind of story holds for today. Health experts have said for some time that dietary fat is a leading factor in cancer of the breast, prostate, colon, and ovary. But it is difficult for most doctors in clinical medicine to consider prevention.

"In 1952, I began working at the Sloan-Kettering Institute, where I founded the Division of Epidemiology. And for 20 years, I undertook epidemiological studies in many other kinds of cancers and began more detailed work on the chemistry and biology of tobacco smoke.

"In the late 1960s, Dr. Dietrich Hoffmann joined me from Germany. Over the following several years, we published numerous studies on tobacco carcinogenesis. I later became interested in many other aspects of cancer etiology, with particular emphasis on nutrition. In 1969, I thought it should be possible to create an institute totally dedicated to cancer prevention and etiology. So I founded the American Health Foundation, where I am today. We have been fortunate over these many years to receive significant support from NIH, particularly from NCI. We have a staff of close to 250 people. Our facilities include a free-standing lab in Westchester, New York, health-promotion and child-health-education activities in Manhattan, and a comprehensive cancer prevention center in Valhalla, New York, where we relate basic research to health promotion. I feel very strongly that there should be more centers like ours dedicated to the prevention of cancer and not strictly to clinical cancer work."

—Suzanne Fogle
that the change has been due to an external factor, or group of factors, nationally prevalent but applicable to men more and over a longer period than to women.

Influence of Tobacco.—Since in a small percentage of cases cancer of the lungs occurs in nonsmokers and minimal smokers and since it obviously does not develop in every person who has been a heavy smoker for a long time, it is apparent that smoking cannot be the only etiologic factor in the induction of the disease. From the evidence presented, however, the temptation is strong to incriminate excessive smoking, in particular cigarette smoking, over a long period as at least one important factor in the striking increase of bronchiogenic carcinoma for the following reasons: (1) it is rare to find a case of epidermoid or undifferentiated carcinoma in a male patient who has not been at least a moderately heavy smoker for many years; (2) the use of cigarettes is much greater among patients with cancer of the lungs than among other patients of the same age and economic groups; (3) the sex distribution of cancer of the lungs roughly corresponds to the ratio of long-term smoking habits of the two sexes (see section on “Duration of Smoking”); (4) the enormous increase in the sale of cigarettes in this country approximately parallels the increase of bronchiogenic carcinoma.

Amount of Smoking.—The data have clearly shown that the average patient with cancer of the lungs smokes much more heavily than the average patient of the same age and economic group with some other disease. This contrast becomes even greater if our observation of Mormons is considered, who as a group smoke far less than the general hospital population; Mormons with cancer of the lung were, with one exception, considerable smokers.

The fact that patients with bronchiogenic cancer in their forties and fifties had smoked more heavily than those in whom the cancer developed at a later age may indicate that the greater the irritation the sooner will cancer develop in a susceptible person. Such an observation obviously does not apply to the individual case but rather to the age groups taken collectively. Too few patients below the age of 40 have been seen in order to evaluate this age group.

In general it appears that the less a person smokes the less are the chances of cancer of the lung developing and, conversely, the more heavily a person smokes the greater are his chances of becoming affected with this disease.

Type of Tobacco.—The majority of patients with cancer of the lungs are cigarette smokers rather than pipe or cigar smokers, the ratio being over and above that found in the general population. This fact may be due to one of the following reasons:

1. Cigarette smoke is more frequently inhaled than is that of either pipes or cigars. Obviously the lungs of an inhaler are exposed to a greater concentration of smoke than those of a person who does not consciously inhale.

2. Because of the greater physical and economic convenience, more persons are heavy smokers of cigarettes than of either pipes or cigars. Among the latter one finds more minimal and light smokers than among the former.

3. Certain irritative substances may be present in cigarettes in greater amounts than in pipes or cigars. The role of paper, the use of insecticides during the growth of the tobacco and other ingredients warrant further research in this regard.

Duration of Smoking.—One of the chief reasons many investigators have thought that tobacco has no effect on the development of cancer of the lungs has been the belief that women today smoke as much as men and that if tobacco plays a role the sex ratio of the disease should be about equal. The data presented demonstrate that it makes little difference how many women smoke today or have smoked for the past ten years, since results have shown that over 96 per cent of patients with cancer of the lungs have smoked for more than twenty years and that over 80 per cent have smoked for more than thirty years.

It is, of course, difficult to tell whether the important point in this regard is the fact that these persons have smoked for many years or that they have been heavy smokers for a brief period, because we have noted that also among the general male hospital population nearly all smokers have been smoking since their youth. For this reason it is difficult to evaluate the one case in our study in which the patient smoked only from his forty-fifth to
his fifth year, at which time clinical signs of cancer developed. If we may judge from control data on women, it would appear that a long duration of smoking is at least one important factor in the induction of cancer of the lungs. The relatively low incidence of the condition in women might be explained by the fact that few women in the cancer age have smoked for an extensive period.

On the basis of a twenty year period of smoking, it may be of interest to note that, while only 1.2 per cent of the women were excessive or chain smokers, by contrast 19.1 per cent of the male controls were in those smoking groups, a ratio which points in the same direction as the sex ratio of lung cancer.

**Lag Period.**—If smoking is to be regarded as an important etiologic factor in the development of cancer of the lungs, apparently a time lag exists for this disease as well as for carcinoma of the bladder, known to occur years after cessation of exposure to aniline. We have now seen 3 cases in which clinical signs of cancer of the lung appeared ten years or more after the patient stopped smoking. The 3 patients had smoked for thirty years or more, and none gave a history of occupational or other irritative exposures. Two of them had stopped smoking because of a bothering chronic cough and 1 because of concomitant heart disease. In 1 of the patients, a 67 year old warehouse clerk, clinical symptoms of cancer developed thirteen years after the cessation of smoking. The phenomenon of the lag period is of course well known in cancer research.

**Adenocarcinoma in Men.**—Since the great increase in cancer of the lungs has mostly involved the epidermoid and undifferentiated carcinomas, it would appear that the exogenous factors possibly affecting these types of cancer play a lesser role, if any, in the induction of adenocarcinomas of the lung in men. As yet we have not seen a sufficient number of cases of this type of cancer to warrant definitive conclusions. It appears, however, that on the basis of present data one is more likely to find nonsmokers or minimal smokers with this type of cancer than with the other types. At the same time, however, the percentage of chain smokers among men with adenocarcinomas of the lung is greater than among the general hospital population. It seems, therefore, that tobacco smoke has also some influence on the induction of adenocarcinoma in men, even though, as judged from the incidence, the influence on this type is much less marked than on the other types of bronchiogenic carcinoma.

**Cancer of the Lungs in Women.**—Many observers have commented on the fact that bronchiogenic carcinoma, while on the increase among both men and women, is increasing more rapidly among men. In 100 consecutive cases collected by Lindskog in 1938 to 1943 the ratio was 4.5 to 1, and in another series collected in 1947 and 1948 the ratio had reached 24 to 1. At Barnes Hospital the ratio in our last 160 cases has been 18.5 to 1. This shift in ratio has been noted in varying proportions throughout the country. Such a radical change warrants a careful analysis.

The insufficient number of cases of cancer of the lungs in women in our survey does not allow definite conclusions at this time. So far, however, smoking seems to have had no apparent effect on the incidence of adenocarcinoma in women. It is of great interest that we have observed 10 cases of epidermoid and undifferentiated carcinoma of the lungs of women who were nonsmokers with no history of occupational or other irritative exposure. This percentage of nonsmokers in women with cancer of the lung is much higher than that found among men. Proper explanations for this finding remain to be advanced. At the same time it appears strongly sugges-

---

**CONCLUSION AND SUMMARY**

1. Excessive and prolonged use of tobacco, especially cigarettes, seems to be an important factor in the induction of bronchiogenic carcinoma.

2. Among 605 men with bronchiogenic carcinoma, other than adenocarcinoma, 96.5 per cent were moderately heavy to chain smokers for many years, com-
pared with 73.7 per cent among the general male hospital population without cancer. Among the cancer group 51.2 per cent were excessive or chain smokers compared to 19.1 per cent in the general hospital group without cancer.

3. The occurrence of carcinoma of the lung in a male nonsmoker or minimal smoker is a rare phenomenon (2.0 per cent).

4. Tobacco seems at this time to play a similar but somewhat less evident role in the induction of epidermoid and undifferentiated carcinoma in women. Among this group a greater percentage of nonsmokers will be found than among the men, with 10 of 25 being nonsmokers.

5. Ninety-six and one-tenth per cent of patients with cancer of the lungs who had a history of smoking had smoked for over twenty years. Few women have smoked for such a length of time, and this is believed to be one of the reasons for the greater incidence of the disease among men today.

6. There may be a lag period of ten years or more between the cessation of smoking tobacco and the occurrence of clinical symptoms of cancer.

7. Ninety-four and one-tenth per cent of male patients with cancer of the lungs were found to be cigarette smokers, 4.0 per cent pipe smokers and 3.5 per cent cigar smokers. This prevalence of cigarette smoking is greater than among the general hospital population of the same age group. The greater practice of inhalation among cigarette smokers is believed to be a factor in the increased incidence of the disease.

8. The influence of tobacco on the development of adenocarcinoma seems much less than on the other types of bronchogenic carcinoma.

9. Three independent studies have resulted in data so uniform that one may deduce the same conclusions from each of them.

ADDENDUM

Since the data presented in this paper were tabulated, 45 additional interviews of male patients with epidermoid or undifferentiated cancer of the lung have been obtained. Eight of these patients have been interviewed by Dr. J. L. Ehrenhaft from the University of Iowa Hospital. 9 were given our questionnaire by Lt. Col. J. M. Salter from Fitzsimons General Hospital and 7 were reported on by Dr. E. J. Shabart from the Veterans Administration Hospital, Hines, Ill. Among these 24 cases there were no nonsmokers or light smokers, 7 heavy smokers, 13 excessive smokers and 4 chain smokers. Twenty-one additional patients have been interviewed by Miss Croninger on the Barnes Hospital Chest Service. Among these there were 1 nonsmoker (a 72 year old blacksmith), 10 heavy smokers, 6 excessive smokers and 4 chain smokers. These 45 cases, which include reports independently made at two additional centers (University of Iowa and Fitzsimons General Hospital), show the same trend noted in the larger series.
